Machine Learning for Sports Betting

Accuracy, calibration and trading performance in the NBA and English Premier League

Aman Dhillon and Panagiotis Housos

Supervisor: Daniel Totouom-Tangho

October 23, 2026

Final project report

Research question. Does selecting a prediction model for calibration, rather than accuracy, improve the performance of an explicit sports-betting rule? We implement the same research framework in a binary NBA market and a three-outcome Premier League market, while preserving their different data, selection dates and capital-allocation conventions.

Main findings. In the supplied NBA 2018/19 simulation, the accuracy-selected SVM returns 25.03% on starting capital with flat stakes but loses 55.11% with one-eighth Kelly. The calibration-selected logistic model returns 0.98% with flat stakes and loses 35.00% with Kelly. Nine separately initialised logistic-only seasons have negative average capital returns for both selection objectives. In the locked EPL experiment, neither branch selects an admissible validation trading rule, so both primary test policies hold cash. The secondary fixed-stake calibration branch's 0.41% stake ROI has an interval crossing zero. Subsequent EPL player models do not improve on their matched team controls.

Evidence standard. Original saved outputs are distinguished from independent calculations. The NBA logistic replay reconciles to the supplied bankrolls; the SVM refit does not, and its original numbers remain explicitly source-reported. Historical profits are not presented as executable or prospectively validated investment returns.

Contributions: Aman Dhillon — NBA; Panagiotis Housos — Premier League.

1 Common methodology

1.1 Research question and experimental scope

The September 30 proposal asks whether selecting a sports-outcome model for calibration, rather than classification accuracy, improves betting returns. Aman Dhillon implements the NBA component and Panagiotis Housos the English Premier League (EPL) component. Both studies connect pre-game statistical features to outcome probabilities and then to explicit betting rules. A good classifier, a well-calibrated probability forecast and a profitable betting strategy are different objects: a profitable bet also requires a sufficiently favourable price and a viable stake.

The motivating reference is Walsh and Joshi's study of NBA model selection [1]. Its 2025 corrigendum supersedes the original numerical claims: corrected mean capital returns are -9.77% for calibration-based selection and -26.78% for accuracy-based selection, and Kelly betting can lose despite calibration [2]. Consequently, improved profitability is tested rather than assumed. The NBA experiment is a replication and rolling extension; the EPL experiment adapts the pipeline to three outcomes and subsequently adds exploratory team, xG and player-feature comparisons. Multi-book line shopping and mathematical arbitrage screening are implemented in the EPL component, not the supplied NBA notebook's single-book replay.

1.2 Pre-game information and chronological model selection

For fixture i, let Y_i denote the realised result and X_i the feature vector constructed from earlier completed games. NBA results are binary, $Y_i \in \{H, A\}$; EPL results include draws, $Y_i \in \{H, D, A\}$. Team features describe earlier opponent-relative performance and prior-season strength. The NBA code applies shifted expanding averages within each team-season. EPL features include season-to-date and recent form, with source-coverage controls and, in the extensions, lagged xG and FPL player aggregates. Target-game scores, appearances and minutes cannot be predictors of that same game.

The initial experiments use separate accuracy- and calibration-driven branches, each considering logistic regression, random forests, support vector machines and multilayer perceptrons. Distribution screening, Spearman redundancy filtering, sequential forward selection and TPE hyperparameter search precede the later betting evaluation. These are shared methodological ideas, not identical settings. All normalisation statistics are estimated in the appropriate earlier fitting block. Table 1 records differences that matter for interpreting the results.

Selecting a model for small calibration error is not the same as fitting a post-processing calibrator. In the first EPL study, a scalar temperature is fitted on a disjoint season for every candidate in both branches, $p_{ik}(T) = \exp(z_{ik}/T)/\sum_j \exp(z_{ij}/T)$, where z_i are the saved model scores [3]. The NBA notebook instead selects using its calibration criterion. Neither implementation implies that probability calibration guarantees value against bookmaker prices.

1.3 Forecast scores and market benchmarks

Let p_{ik} be the predicted probability of outcome k and $y_{ik} = \mathbb{1}\{Y_i = k\}$. Classification accuracy uses the highest-probability outcome. Probability quality is assessed using log loss and Brier loss:

$$\mathrm{LL} = -\frac{1}{n}\sum_i \log p_{i,Y_i}, \qquad \mathrm{Brier}_{\mathrm{EPL}} = \frac{1}{n}\sum_i \sum_{k\in\{H,D,A\}} (p_{ik} - y_{ik})^2. \tag{1}$$

The NBA binary Brier convention is $n^{-1}\sum_i (p_{iH} - y_{iH})^2$. Its values therefore should not be ranked directly against the unscaled three-class EPL Brier score. Log-loss levels also depend on the outcome space and base rates; model–market differences are interpreted within each league.

Table 1: Shared framework and league-specific implementation.

Aspect	NBA	Premier League
Outcome and feature eligibility	Home/away; both teams must have at least ten earlier season games.	Home/draw/away; missing histories retained with coverage and fitting-only missing-value handling.
First selection chronology	Train 2014/15–2015/16; tune 2016/17; choose model family on 2017/18; bet 2018/19.	Train 2014/15–2020/21; tune 2021/22; calibrate 2022/23; select family 2023/24; choose threshold 2024/25; evaluate 2025/26.
Calibration treatment	Selection by a 20-bin binary ECE with an occupancy penalty; no separate held-out temperature fit.	Selection by mean three-class ECE with ten bins; both branches receive held-out temperature scaling.
Extensions	Nine rolling windows reselect features but fit logistic regression in both branches.	Four rolling evaluation seasons compare fixed feature groups; the later player-model study adds logistic and boosted trees.
Prices and outcome choice	One saved home/away moneyline pair; test home value first, otherwise away value.	Saved individual-book quotes and a Bet365 reference; select the allowed outcome with maximum estimated return.
Capital allocation	Sequential per-game settlement; fixed 100 or one-eighth Kelly from 10,000 initial capital.	Same-date opening-cash allocation; fixed, cash-fraction and capped fractional-Kelly configurations; 100,000 initial capital in the expanded account comparison.

For probability bin b of class k, calibration error compares observed frequency $\bar{y}_{kb}$ with mean forecast $\bar{p}_{kb}$:

$$\mathrm{ECE}_k = \sum_b \frac{n_{kb}}{n} |\bar{y}_{kb} - \bar{p}_{kb}|. \tag{2}$$

The EPL implementation averages this quantity over all three classes and reports ten-bin ECE, with five- and fifteen-bin sensitivity summaries. The NBA implementation uses the home-win probability and twenty equal-width bins; it replaces the score by 1 if fewer than 80% of bins are occupied. This is an optimisation penalty, not an observation of literal 100% miscalibration. The two ECE scales are not interchangeable. Constant forecasts may have small unpenalised ECE while offering little match-specific information.

For decimal odds O_{ik}, the implied probability is $1/O_{ik}$. A reference book's overround and proportional margin-normalised benchmark are

$$A_i = \sum_k O_{ik}^{-1}, \qquad q_{ik} = \frac{O_{ik}^{-1}}{A_i}. \tag{3}$$

The benchmark q_i is a market estimate, not known truth. NBA American moneylines m are converted to decimal odds as $1 + m/100$ for $m > 0$, and $1 + 100/|m|$ for $m < 0$. EPL line shopping uses the largest eligible archived individual-book quote for each outcome; a separate reference-price replay recomputes selections and stake sizes. An archived combination with $\sum_k 1/O_{ik}^* < 1$ is a mathematical arbitrage candidate only. Without simultaneous accepted fills, aligned settlement and known costs, it is not an executed risk-free profit.

1.4 Bet selection, stake sizing and accounting

For selected outcome probability p_i and decimal odds O_i, estimated return per unit staked is $e_i = p_i O_i - 1$. The NBA rule takes a home bet when $p_{iH} > 1/O_{iH}$, otherwise an away bet when $1 - p_{iH} > 1/O_{iA}$; it does not

maximise across both qualifying sides. The principal EPL value rules instead choose the largest admissible e_i and require a declared threshold. Thresholds and filters are reported with their respective strategies; the first EPL validation-selected rules can remain entirely in cash.

With stake s_i, the realised net payoff and the model-implied positive and negative cash components are

$$\pi_i = s_i\{O_i \mathbb{1}(\text{win}) - 1\}, \tag{4}$$

$$G_i = p_i s_i (O_i - 1), \qquad L_i = (1 - p_i)s_i, \qquad G_i - L_i = s_i e_i. \tag{5}$$

Expected gains and losses use model probabilities at the recorded stakes; they are distinct from average realised winning gains and losing stakes. They are reported only where the supplied prediction-and-trade evidence supports their calculation.

Full Kelly requests fraction $f_i^* = (p_i O_i - 1)/(O_i - 1)$ of available capital. Fractional Kelly multiplies this by λ, with any declared per-bet cap c: $s_i = B \min\{c, \lambda \max(0, f_i^*)\}$. The NBA notebook uses $\lambda = 1/8$ and caps only at available cash. EPL configurations specify their Kelly fraction, per-bet cap and any total date-level budget. A fixed stake of 1,000 in a 100,000 account equals 1% of *initial* capital, not 1% of a changing bankroll. EPL same-date requests are reduced together to fit opening cash before any same-date winnings settle. The NBA source simulator processes games sequentially, so its funding convention is retained and disclosed rather than silently replaced by the EPL convention.

For total profit $P = \sum_i \pi_i$ and turnover $V = \sum_i s_i$, the final report uses two explicitly different denominators:

$$\text{stake ROI (yield)} = P/V, \qquad \text{capital return} = P/B_0. \tag{6}$$

The supplied NBA material calls the second quantity "ROI"; it is relabelled as capital return for consistency. Hit ratio is wins divided by settled bets; trade frequency is bets divided by priced match opportunities. Drawdown is the largest proportional fall from a prior account peak. Undefined no-trade ratios remain unavailable. Where a display rebases an account to 100,000, all cash amounts and stakes are multiplied by the same constant; reported percentage returns do not change. Separately reset NBA seasons are not presented as one funded continuous investment account.

1.5 Interpretation and evidence limits

The completed historical experiments are comparisons of recorded designs, not new live trading records. Repeatedly examined EPL extensions are explicitly exploratory. NBA annual variation and EPL whole-date conditional bootstrap intervals do not remove feature, model or strategy selection uncertainty. Bookmaker probabilities are competitive benchmarks, and favourable model expected value is not independent evidence of a realised edge. Neither a positive season nor a historical rank establishes a reliable betting policy. The NBA results below preserve the supplied notebook and report evidence; the EPL section retains the frozen prediction, trade and cash-flow artifacts.

2 NBA results

2.1 Data, features and selection roles

The NBA component uses the supplied team-game CSV and season tables in `OddsData.sqlite`. The CSV contains 33,316 team records and 16,658 distinct raw games across 2010/11–2023/24. After pairing teams and excluding each club's first ten season appearances, 14,471 games remain; both teams have at least ten earlier observations in each retained fixture. The core betting season, 2018/19, contains 1,074 eligible games with a complete matched moneyline pair. The saved 58.5% home-win rate refers to the training subset, not to all 14,471 games.

The initial feature set consists of 25 opponent-relative box-score statistics and a previous-season win-rate difference. Shifted expanding means exclude the target game. The training–validation KS screen removes offensive rebounds; 25 candidates remain. The Spearman screen retains nine variables. Forward selection uses offensive rating and three-pointers made for the calibration branch, and adds prior-season win percentage and turnovers for the accuracy branch. These are different predictor subsets, not a single model scored two ways.

Table 2: NBA chronology and sample sizes in the supplied core experiment.

Role	Seasons	Games
Initial training	2014-15, 2015-16	2,145
Feature / hyperparameter validation	2016-17	1,074
Model-family selection	2017-18	1,075
Betting evaluation	2018-19	1,074

There are 30 Optuna trials per family and branch. The source averages predictions over ten random seeds for model-family assessment and the final betting prediction. The season called *test* in the notebook is used to select the family: it is therefore a model-selection season in this report. Only the subsequent 2018/19 betting season follows all these choices.

Table 3: NBA model-family selection, 2017/18. The two columns describe different branch-specific fitted variants; they are not joint scores of one model.

Family	B: ECE (2 inputs)	C: accuracy (4 inputs)
Logistic regression	4.31%	65.30%
Random forest	5.68%	65.40%
Neural network	4.65%	65.49%
SVM	4.40%	66.33%

Calibration selection chooses logistic regression; accuracy selection chooses the SVM. The calibration branch's selection ECE is 4.31%, while the accuracy branch's selection accuracy is 66.33%. They must not be described as the accuracy and ECE of a single predictor. *Evidence:* `MLSports/Data.ipynb: cells1--16(zero-based)`

2.2 The 2018/19 betting simulation

Each native account starts with 10,000 monetary units. Flat staking requests 100 per qualifying game, equal to 1% of *initial* capital. One-eighth Kelly varies the request with the predicted edge and available cash; unlike the EPL rules, no additional 2% per-bet ceiling is imposed. The simulator checks home value before away

value and settles games sequentially. Its output labelled "ROI" is profit divided by starting capital. Table 4 uses the unambiguous term *capital return*.

Table 4: Original saved NBA betting results, 2018/19; initial capital 10,000.

Branch / model	Stake	Final capital	Capital return	Bet freq.	Hit ratio
Calibration / LR	Flat 100	10,097.74	0.98%	85.3%	38.0%
Calibration / LR	1/8 Kelly	6,500.40	-35.00%	85.3%	38.0%
Accuracy / SVM	Flat 100	12,502.98	25.03%	88.6%	34.9%
Accuracy / SVM	1/8 Kelly	4,488.59	-55.11%	88.6%	34.9%

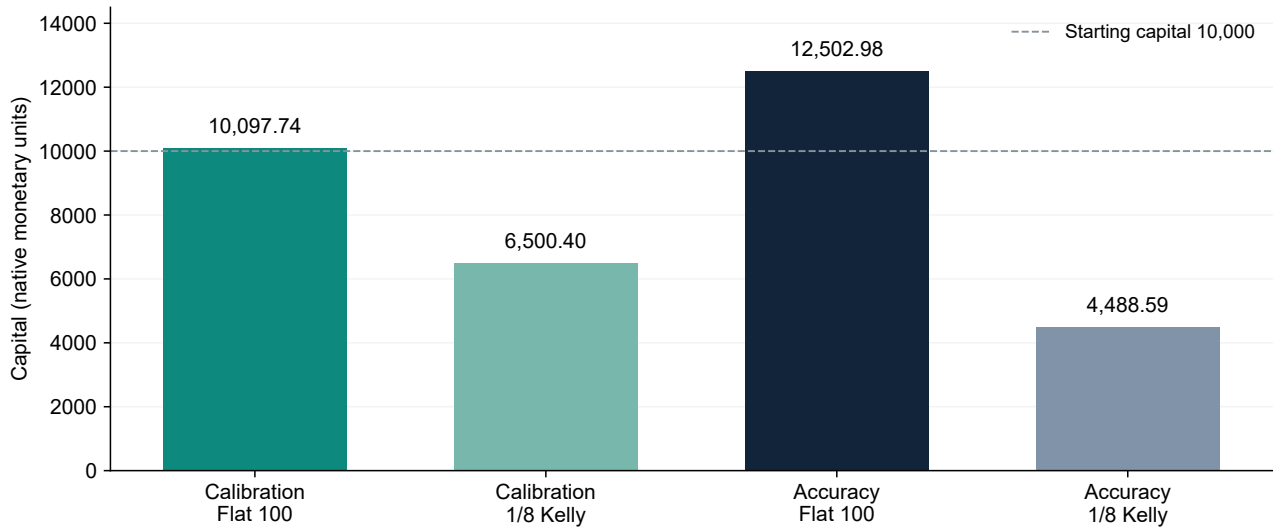

Figure 1: Ending capital of the four original saved NBA 2018/19 strategies. These are endpoint comparisons, not a reconstructed SVM wealth path. LR = logistic regression. The SVM numbers are source-reported; their supplied-parameter refit does not reconcile.

The accuracy-selected SVM's positive flat-stake result and negative Kelly result come from different exposure sizes, not different prediction models. For the calibration-selected logistic model, flat stakes finish only slightly above the starting account, while Kelly finishes substantially below it. Thus the source evidence does not support treating calibration selection as a guarantee of profitable stake sizing.

The saved betting-season prediction accuracy is 65.27% for logistic regression and 64.80% for the SVM, distinct from their earlier selection scores. The notebook's SVM calibration score is replaced by a bin-coverage penalty; it is not an observation of literal 100% calibration error.

2.3 What the independent replay verifies

A fixed-parameter audit uses the supplied feature subsets and stored hyperparameters with ten-seed averaging. It performs no new feature search, hyperparameter search or strategy optimisation. Both logistic account endings match the notebook to the printed cent, and its saved accuracy and ordinary 20-bin ECE also reconcile. In contrast, the SVM refits reach the supplied iteration limit and produce different predictions and bankrolls. Original library versions and serialized fitted weights were not supplied. We retain the original SVM results as *reported* and do not silently replace them with the mismatching refit.

Table 5: Independently computed metrics on the same 1,074 NBA betting fixtures. The logistic reconstruction reconciles; the bookmaker benchmark is calculated directly from the provided odds.

Predictor	Accuracy	ECE 20	Log loss	Binary Brier
Matched logistic	65.27%	4.27%	0.6172	0.2141
Normalised odds	66.95%	4.73%	0.5954	0.2045

The market probabilities have lower log loss and binary Brier loss and higher accuracy than the reconciled logistic predictor. The logistic model, however, has lower ordinary ECE in this season. We therefore do not claim that the market dominates every metric in every season. In particular, a small global calibration statistic does not establish a profitable advantage on the bets selected against bookmaker prices.

Table 6: Additional metrics supported by the cent-matched NBA logistic replay; native 10,000-unit account. Expected components use the model's probabilities, not observed win/loss averages.

Stake	Bets	Hit	Freq.	G/trade	L/trade	Stake ROI	Max DD
Flat 100	916	37.99%	85.29%	83.70	54.22	0.11%	29.09%
1/8 Kelly	916	37.99%	85.29%	103.43	54.37	-3.26%	59.45%

Only the reconciled logistic subset supports these extra trade-ledger statistics. Corresponding SVM turnover, expected payoff components and drawdown are not imputed from the original rounded headline outputs. *Evidence:* `final_deliverables/nba_core_replay/summary.json`

2.4 Nine independently restarted seasons

The rolling extension contains nine betting seasons, 2014/15–2022/23, and 9,344 priced games. It reselects features in each window, but uses logistic regression for *both* branches. It does not repeat the core four-family hyperparameter tournament. Each seasonal diagnostic restarts at 10,000 and requests flat stakes of 100.

Table 7: Saved NBA annual capital returns, flat 100 from a fresh 10,000 each season. Values are preserved at the source's two-decimal precision.

Season	Games	B inputs	C inputs	Cal. capital return	Acc. capital return
2014-15	1,072	2	7	-65.30%	-16.78%
2015-16	1,073	5	4	-17.73%	-12.31%
2016-17	1,074	4	4	57.42%	46.75%
2017-18	1,075	4	6	-100.00%	-100.00%
2018-19	1,074	2	4	2.08%	12.25%
2019-20	906	5	4	85.58%	100.86%
2020-21	924	6	6	-31.59%	-33.85%
2021-22	1,073	3	7	-83.67%	-89.28%
2022-23	1,073	3	3	-2.89%	6.93%

The calibration branch has the higher return in only three of nine seasons. Its reported mean return is -17.34% with sample standard deviation 61.7 percentage points, versus -9.49% and 62.5 points for the accuracy branch. Both 2017/18 accounts exhaust their cash. These nine dependent historical windows are descriptive robustness evidence, not nine independent replications establishing a precise long-run expected return.

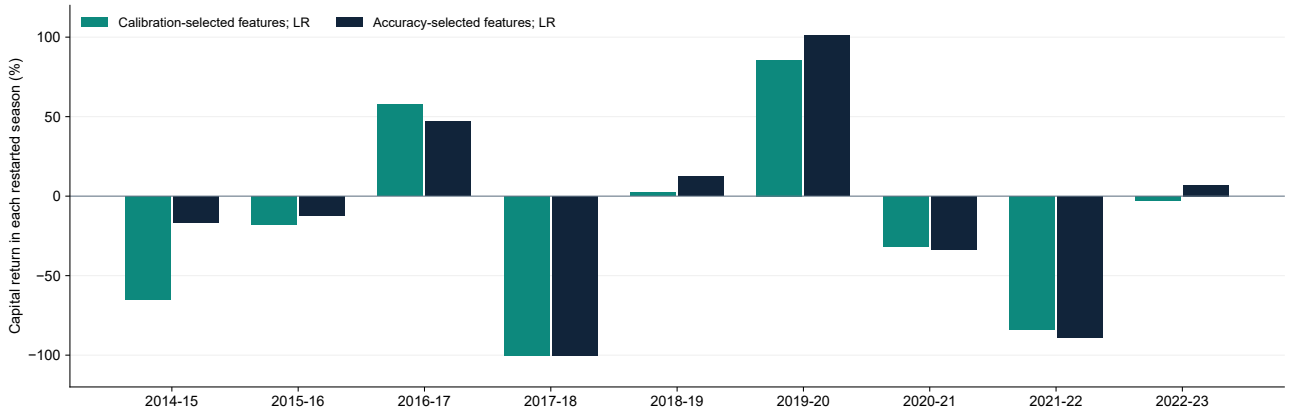

Figure 2: NBA annual capital returns for the rolling logistic-only extension. Every bar represents a separate initial 10,000 account; the bars are not contributions to a continuously funded portfolio.

The source's cumulative display adds cashflows from separately restarted seasons to a previous base. That can create unfunded or negative shadow balances and is not a continuous self-financing bankroll. It is excluded from this report's money-progression evidence. The supplied NBA write-up also describes additional pooled market/fusion analyses whose underlying forecasts are not preserved in the notebook. Those figures are not substituted for the directly reconciled common-fixture comparison above.

3 Premier League results

3.1 Data and adaptation to three outcomes

The EPL component predicts home wins, draws and away wins. The focal universe is the 20 saved 2026/27 Premier League clubs; historical opponents remain context rather than being relabelled as current clubs. This present-day cohort creates selection/survivor limitations. Its 2025/26 matched evaluation contains 374 fixtures, rather than all 380 league fixtures.

Football-Data supplies results, team performance and individual-book odds; Understat supplies team expected-goals histories; Fantasy Premier League (FPL) supplies player records. The expanded player loader reconciles 253,509 historical player-match records in 2016/17–2025/26. The saved October 20 snapshot adds 4,551 current-season rows from 70 completed fixtures and 668 current player summaries. Historical inputs use strictly earlier dates; target participants, target minutes and present-day rosters do not backfill earlier forecasts. Role-based extensions disclose season-fixed position proxies with unverified publication clocks.

3.2 Proposal-aligned accuracy versus calibration experiment

The first locked experiment considers the same four candidate families as the NBA component, with 12 seeded tuning trials per family per branch. Earlier training and tuning are followed by separate calibration, model-selection and trading-validation seasons (Table 1). Both branches receive temperature scaling; the experiment compares selection objectives rather than calibrated versus deliberately uncalibrated predictions.

Accuracy selection chooses an SVM using season-to-date corners difference and recent shots-on-target difference. Calibration selection chooses an MLP using earlier corners conceded. The original xG/player candidates do not survive this small-budget selection path, so this experiment alone cannot establish their incremental value.

Table 8: Locked EPL 2025/26 probability scores on 374 identical fixtures. ECE is mean classwise error with ten bins.

Predictor	Accuracy	ECE 10	Log loss	Brier
Accuracy-selected SVM	48.13%	6.20%	1.0763	0.6446
Calibration-selected MLP	44.39%	4.16%	1.0564	0.6356
Normalised Bet365	48.66%	4.36%	1.0191	0.6120
Training frequencies	42.51%	2.90%	1.0851	0.6566

The calibration-selected MLP has lower ECE, log loss and Brier loss, but lower classification accuracy, than the selected SVM. Normalised bookmaker probabilities have stronger proper losses than either learned model. The frequency baseline's low ECE despite poor log loss also illustrates the limitations of using calibration error alone. Conditional paired intervals for the MLP-minus-SVM ECE and log-loss differences both contain zero; they omit model-selection uncertainty and do not establish a causal calibration effect.

Neither primary policy achieves positive validation profit with at least 30 validation bets. Both therefore select cash: zero test bets, zero turnover and undefined stake ROI. This is the primary locked-policy finding. The secondary 5% edge rule is evaluated separately, with an original 1,000-unit account, flat 10 or capped quarter Kelly.

The MLP's best-price flat-stake ROI of 0.41% is not robust evidence of an edge: its interval crosses zero, its reference-price flat result is negative, and its quarter-Kelly result is negative. Both primary rules remain

Table 9: Secondary EPL 5% edge replay on the test season; native initial capital 1,000. Stake ROI is profit divided by turnover.

Branch / odds	Stake	Bets	Profit	Stake ROI	95% ROI interval
SVM / Best	Flat 10	371	-83.30	-2.25%	[-18.83%, 15.45%]
SVM / Best	1/4 Kelly	371	-377.05	-7.01%	[-23.18%, 11.92%]
SVM / Bet365	Flat 10	365	-186.70	-5.12%	[-20.25%, 11.15%]
SVM / Bet365	1/4 Kelly	365	-433.14	-8.57%	[-23.64%, 8.79%]
MLP / Best	Flat 10	333	13.70	0.41%	[-20.08%, 22.07%]
MLP / Best	1/4 Kelly	333	-153.91	-2.59%	[-20.93%, 17.72%]
MLP / Bet365	Flat 10	314	-23.50	-0.75%	[-19.46%, 19.70%]
MLP / Bet365	1/4 Kelly	314	-170.61	-3.09%	[-20.97%, 16.47%]

in cash. Later presentation accounts scale initial capital and fixed stakes by 100; percentage ratios remain unchanged, while monetary amounts must be labelled with their account basis.

3.3 Exploratory team and player comparisons

The rolling extension uses 1,470 common quoted fixtures in four seasons: 368 in 2022/23, 360 in 2023/24, 368 in 2024/25 and 374 in 2025/26. Each fit uses earlier seasons for training, tuning and calibration. These are new redesigns on already examined outcomes; chronology does not make them a fresh confirmatory test.

The earlier source study crosses logistic and market-residual estimators with team, team+xG, team+FPL and combined inputs. Market-residual models start from normalised bookmaker probabilities and learn regularised feature adjustments. The newer study compares logistic and histogram boosting on matched team controls (19 inputs), player form (96), player form plus projected XI/depth (222), and team plus the full player block (235).

Table 10: Selected pooled EPL comparisons on the same 1,470 fixtures. Best learned means lowest observed pooled log loss, not greatest trading capital.

Predictor	Accuracy	Log loss	Brier
Raw market benchmark	54.42%	0.9662	0.5743
Best learned: odds + team/FPL	54.15%	0.9693	0.5751
Team logistic	52.93%	0.9876	0.5889
Player-form logistic	50.07%	1.0218	0.6114
Class frequency	44.29%	1.0700	0.6471

The raw market has the best pooled proper scores among all 19 comparable series. The strongest learned model uses bookmaker probabilities, so it is not an odds-free team/player forecast. All six new player-based variants have worse pooled log loss than their matched same-algorithm team controls. This is a finding about these particular representations, not a general claim that player information has no value.

3.4 Money progression and the complete strategy comparison

The expanded laboratory specifies 116 distinct combinations of forecast, outcome rule, prices and stakes. They are not 116 independent learning algorithms. Every account begins at 100,000. The common 2025/26 chart contains all 116; the uninterrupted four-season chart contains the 88 configurations with comparable

earlier predictions. The 28 unavailable first-study configurations are not backfilled with models that saw those outcomes.

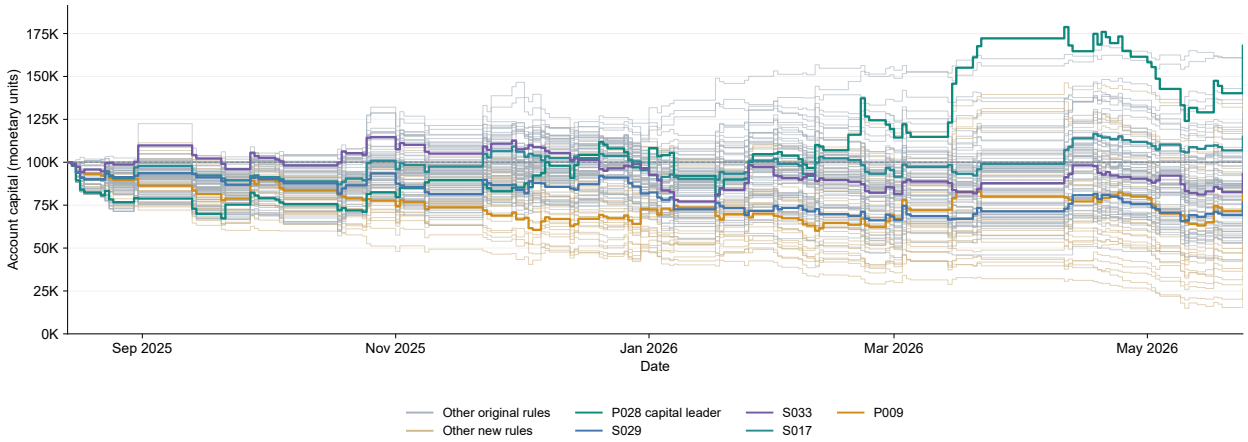

Figure 3: All 116 saved EPL accounts in the common 2025/26 season, each starting at 100,000. A line is one forecast/rule/price/stake combination; overlapping cash paths remain included.

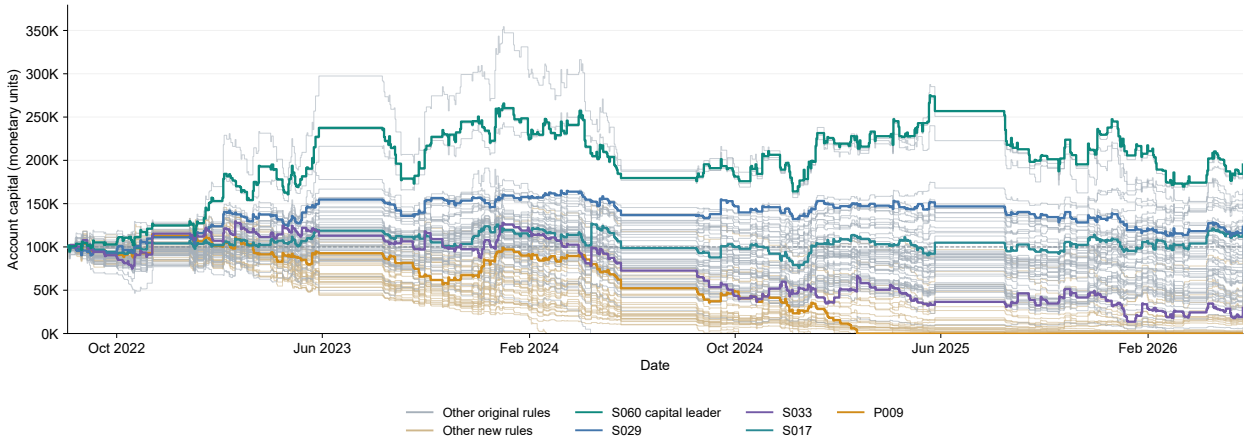

Figure 4: All 88 comparable EPL accounts across four seasons, without annual resets or deposits. Every endpoint reconciles with its saved account metrics.

S029 is the best learned probability model with a flat-stake trading wrapper. S033 is the simplest historical-frequency model, S017 uses team performance, and P009 uses pure player form. Their common 5% value filter and flat 1,000 request make the performance descriptions concrete: 1,000 is 1% of initial capital, not a changing 1% fraction. Requests remain subject to date-start cash allocation.

Among all 116 single-season accounts, 33 profit, 75 lose and eight remain flat. P028 has the highest final 2025/26 capital, 167,925, but loses 83.33% in its uninterrupted four-season account. Among the 88 continuous accounts, 24 profit and 64 lose; 13 exhaust their cash. S060 has the highest ending capital, 195,190, but its conditional ROI interval crosses zero. All 32 new player-study continuous accounts lose money, with 11 reaching zero. Historical ranks are descriptive and do not promote a live betting policy.

Table 11: Representative EPL strategy accounts, uninterrupted 2022/23–2025/26 from 100,000. Expected gain/loss are per-trade model claims.

ID	Bets	Hit	Freq.	Final capital	Stake ROI	G/trade	L/trade	Max DD
S029	1,147	31.04%	78.03%	123,340.00	2.03%	852.95	663.70	31.88%
S033	1,447	23.01%	98.44%	29,760.00	-4.85%	1,739.52	611.96	89.49%
S017	1,241	29.57%	84.42%	119,790.00	1.59%	962.54	648.43	40.35%
P009	944	25.00%	64.22%	0.00	-10.87%	1,098.04	618.22	100.00%
S060	1,186	30.69%	80.68%	195,189.75	2.99%	2,226.45	1,652.54	38.35%
P028	1,328	26.58%	90.34%	16,674.79	-10.67%	628.17	356.67	95.18%

3.5 Prices, operational evidence and joint interpretation

S060's profit is approximately 95,190 at the saved best quotes and 55,952 under a full Bet365 policy replay. Repricing its fixed original exposures instead gives approximately $-30,549$. The latter is a payout attribution; the former recomputes selections and cash sizes. These are different questions, not a pure causal price effect. Quote capture clocks, accepted stake limits and simultaneous fills remain unverified. Mathematical arbitrage flags do not establish executed arbitrage or closing-line value.

The saved operational evidence has a separate October 20 cutoff: four earlier models each classify six of ten resolved fixtures correctly. Forty earlier-model and 80 new-model forecasts concern the same next ten October 23–25 fixtures. This assembly performs no later result settlement, so these figures describe the saved snapshot rather than live October 23 statuses. Missing pre-match quotes and a trade ledger preclude prospective trading ROI.

Taken together, the two league studies support a cautious conclusion. Calibration and accuracy objectives select different models, and stake sizing can reverse a single season's profit. Neither a high classification rate, a low aggregate ECE nor a retrospectively profitable account is sufficient to demonstrate a durable priced-market edge. The completed contribution is the implemented comparison, explicit cash accounting and reproducible evidence, including negative results and the NBA SVM reproduction limit.

[5] A. Dhillon and P. Housos (2026). *Project data, notebook, frozen models and account ledgers*. Supplied NBA material in `ML Sports`; EPL analysis modules and source-hashed exports in the project repository. Detailed input hashes, evidence classifications and replay reconciliation accompany this report.

A Evidence and capital conventions

The authoritative NBA inputs are the supplied notebook's saved outputs, raw box-score CSV, odds database and stored parameter file. The fixed-parameter audit is labelled separately: logistic results reconcile, SVM results do not. The separate NBA report/presentation is not an additional independent sample. Likewise, the supplied EPL PDF is identical to an earlier generated EPL deck; the reviewed player-model export copies an existing forecast ledger rather than issuing another 80 predictions. Source and output hashes identify every consumed artifact. Current locally edited source documents are preserved.

No joint NBA–EPL account or common profitability average is manufactured. NBA native accounts begin at 10,000; the first EPL experiment begins at 1,000; the expanded EPL account comparison begins at 100,000. Capital return and stake ROI have different denominators. Independent annual NBA restarts are not deposits into a continuous account. Model expected gains and losses are probability-weighted components at the recorded stakes, not average realised payoffs conditional on winning or losing.

B Premier League strategy rules and metrics

The following tables preserve every S001–S084 and P001–P032 definition. Fixed amounts stay fixed as capital changes. Cash fractions and Kelly requests use date-start cash. Same-date requests are scaled together to available cash and any declared date cap, without borrowing or using same-date winnings. "Best" denotes the saved best individual-book quote, not verified executable availability. H/D/A means home/draw/away. Exact machine-readable configurations and complete gain/loss, frequency and risk metrics accompany the report.
